Linear magnetoresistance (LMR) occurs in semiconductors as a consequence of strong electrical disorder and is characterized by nonsaturating magnetoresistance that is proportional to the applied magnetic field. By investigating a disordered MnAs-GaAs composite material, it is found that the magnitude of the LMR is numerically equal to the carrier mobility over a wide range and is independent of carrier density. This behavior is complementary to the Hall effect that is independent of the mobility and dependent on the carrier density. Moreover, the LMR appears to be insensitive to the details of the disorder and points to a universal explanation of classical LMR that can be applied to other material systems.

I. INTRODUCTION

Imperfections in materials, such as impurities and defects, alter their electronic structure in a variety of ways. These imperfections provide the backbone of many advanced technological applications, ranging from atomic substitutions in crystal lattices, to nanoscale pinning centers that lend functionality to superconductors and advanced magnetic materials. Although atomic substitution in electronic systems has been thoroughly investigated for more than half a century, research on strongly disordered electronic systems is gaining increased attention. Of major interest is the role played by large-scale disorder on the magnetoelectronic properties of materials. Materials and devices with predictable magnetoresistance (MR) are of current interest for applications such as nonvolatile magnetic memories. It is well known that in homogeneous semiconductors having limited electrical disorder, the MR increases quadratically with increasing magnetic field, but eventually saturates at small fields. On the other hand, in compositionally inhomogeneous semiconductors having strong electrical disorder, the anomalously large MR increases linearly with increasing magnetic field, but does not saturate at high fields. Materials with positive, nonsaturating linear MR (LMR) comprise a distinct class of disordered semiconductors. For example, nonstoichiometric silver chalcogenide of the Ag$_2$Se system exhibit a remarkably large LMR up to magnetic fields as high as $H$=55 T. The cause of this behavior is the presence of insulating or metallic particles embedded in the semiconductor matrix.

Several mechanisms have been proposed to characterize the phenomenon of LMR from geometrical, classical, quantum, and effective medium perspectives. The first model to be applied to LMR was a quantum description by Abrikosov, which examines a small bandgap material subjected to a magnetic field large enough to reach the quantum limit where all the electrons occupy the lowest Landau level. This model also considered the existence of a linear energy dispersion relation similar to that found in single-layer graphite (graphene) at the Dirac point. Alternatively, a classical model developed by Parish and Littlewood examined the characteristic properties of LMR using a two-dimensional (2D) resistor network that mimics inhomogeneous conducting media. This was subsequently expanded to a three-dimensional resistor network. In these classical models the linear dependence of the magnetoresistance is linked in a simple manner to electrical disorder. A strong magnetic field forces a significant portion of the current to flow in a direction perpendicular to the applied voltage and thereby provides a linear-in-$H$ Hall resistance contribution to the effective magnetoresistance.

Here we describe the correlation of linear magnetoresistance to the fundamental electrical properties of a strongly disordered semiconductor system. The MR as a function of applied magnetic field is determined from the field-dependent transverse resistance $R(H)$ as

$$MR(H) = \frac{[R(H) - R(H = 0)]}{R(H = 0)}.$$

We find large LMR in a quasi-2D system of MnAs nanoparticles in a GaAs matrix. The magnitude of the LMR is found to be numerically equal to the magnitude of the macroscopic carrier mobility over a wide range of temperature and mobility. This equality,

$$MR(T) = \mu(T)H,$$

is obeyed despite the fact that the carrier concentration changes by several orders of magnitude as a function of temperature. Since LMR is governed by carrier mobility and independent of carrier density, it is complementary to the classical Hall effect that is governed by the carrier concentration and is independent of carrier mobility. In addition, by examining different samples with a variety of disorder, the link between LMR and mobility does not appear to be affected by the specific details of the disorder, such as the size and concentration of the disordered regions. These results point to a universal description of MR in semiconductors with strong local disorder, offering insights for designing new MR systems.

Transverse MR and Hall measurements were carried out on composite films containing self-assembled MnAs metallic nanoparticles embedded in a GaAs matrix. Samples were fabricated from thin layers (20–50 nm) of homogeneous Ga$_{1-x}$Mn$_x$As, $x=0.1$, grown by low-temperature molecular-beam epitaxy (MBE) on GaAs substrates at a temperature of 250 °C. MnAs nanoparticles formed in the films by self-assembly when annealed at temperatures in the range 500–700 °C for 30 min in the MBE chamber in an arsenic flux of vapor pressure of 10$^{-6}$ torr. A variety of nanoparticle diameters and densities were synthesized with Mn content ranging from $x=0.06$ to 0.10. Annealing temperatures in the range 570–670 °C all led to a robust LMR response. The composite structures were examined by superconducting quantum interference device (SQUID) magnetometry, scanning electron microscopy (SEM), atomic force microscopy, and x-ray diffraction. The transverse MR was measured in magnetic fields applied perpendicular to both the current direction and the plane of the film. The inset of Fig. 1 is a SEM image showing MnAs nanoparticles with diameters ranging from 20 to 80 nm with an average of approximately 50 nm. We note that the metallic MnAs nanoparticles can be ferromagnetic or superparamagnetic, depending on the size of the particles, but the magnetism does not affect the MR for $T>50$ K. However, it is the difference in the conductivity of the particles relative to the matrix that is essential in achieving LMR.

The electrical transport properties of a 20-nm-thick MnAs-GaAs composite film are shown in Fig. 1. Conduction in the film was found to be dominated by a high density of holes in the GaAs matrix. Figure 1(a) plots the density of holes as a function of temperature, $p(T)$, obtained from Hall measurements. Near room temperature, the hole density is thermally activated from Mn acceptor sites of density $p_A=4\times10^{19}$ cm$^{-3}$, with an activation energy of $E_A=108$ meV. For decreasing temperature the density decreases as the holes become trapped on the acceptors. Figure 1(b) plots the mobility of the holes as a function of temperature, $\mu(T)$, obtained from Hall measurements. Near room temperature, the hole mobility is $\mu_h=100$ cm$^2$/V·s and increases for decreasing temperature due to reduced phonon scattering. Below $T=50$ K the mobility decreases sharply and coincides with the rapid freeze out of the carriers.

III. MAGNETORESISTANCE RESULTS

The magnetoresistance of a composite film is plotted in Fig. 2 as a function of applied magnetic field $H$ for various temperatures. The transverse MR, which is positive and is an even function of the applied magnetic field, transitions from a quadratic field dependence at low fields to a linear dependence at higher fields. The high-field MR was found to be linear in $H$ at all temperatures $20$ K $\leq T \leq 300$ K. At the highest field, $H=14$ T, the MR increased from 14% at room temperature to nearly 100% at $T=25$ K.
data is a power law of the parameters, \( \text{MR} \) is commensurate with the rapid carrier freeze out. From Fig. 3, the MR slope and the hole mobility have identical power-law dependencies, \( d\text{MR}/dH\propto 1/T^{1.85} \). The dashed line marks the temperature where the carrier mean-free path is equal to the average nanoparticles spacing, illustrated in the insets.

by plotting the temperature dependence of the slope of the linear portion of the MR response over the range \( 5 \text{K} \leq H \leq 14 \text{ T} \). Figure 3 shows a plot of the slope \( d\text{MR}/dH \) as a function of inverse temperature, indicated by the solid circles. The straight line is a fit to the data and follows a power-law dependence given by \( d\text{MR}/dH \propto 1/T^{1.85} \). The seminal connection between the LMR and the carrier mobility is demonstrated by comparing the temperature dependencies of \( d\text{MR}/dH \) with the hole mobility \( \mu_h \), shown by solid squares. It is remarkable that the MR slope and the hole mobility have identical power-law temperature dependencies over the entire temperature range \( 50 \text{ K} \leq T \leq 300 \text{ K} \). Another striking similarity between the LMR and the carrier mobility is the saturation behavior at low temperatures, where both have a common maximum near \( T \approx 40 \text{ K} \). Below \( T=50 \text{ K} \) the mobility is no longer dominated by phonon scattering and the turnover of the data is commensurate with the rapid carrier freeze out. From Fig. 3 it is clear that the identical temperature dependencies of the LRM and the mobility unambiguously demonstrate that the magnetoresistance is \textit{linearly proportional} to carrier mobility. Furthermore, by adjusting the scales to overlap the two sets of data, we obtain numerical equality between the magnitudes of the parameters, \( \text{MR}(T) = \mu(T)H \), a remarkably universal result. It is also significant that this relation holds while the carrier density varies by several orders of magnitude, thus leading to the conclusion that the linear magne-
terminal van der Pauw resistors was used since two-terminal resistors are inadequate to describe a system containing a Hall-effect component. For an infinite network of nonidentical resistors the MR was found to be linear in $H$ for a magnetic field directed perpendicular to the lattice. This model predicts that the MR is dominated either by the average mobility, $\langle \mu \rangle$, or by the width of the mobility distribution, $\Delta \mu$. For a wide mobility distribution, $\Delta \mu / \langle \mu \rangle > 1$, both MR and $H_{CR}$ are expected to be a function of the width of the mobility variation $\Delta \mu$. This behavior was assigned to $\text{Ag}_2\text{Se}$, where the average mobility vanished, $\langle \mu \rangle = 0$, as a result of having equal proportions of electron and hole regions.\(^9\) On the other hand, in the regime of percolating conductivity between silver grains in $\text{Ag}_2\text{Se}$, the average mobility vanished, $\langle \mu \rangle = 0$, as a result of having equal proportions of electron and hole regions.\(^9\)

Finally, we note a connection between the mean-free path of the carriers and length scale of the disorder. At higher temperatures, $T > 50$ K, the carrier mean-free path is dominated by phonon scattering and $\ell_{mfp} \sim 10^{-10}$ nm. Here, the mean-free path is smaller than the average MnAs nanoparticle separation in the system, $(d) \sim 10^{2}$ nm and results in the close overlap of the LMR and mobility seen in Fig. 3 above $T=50$ K. On the other hand, at low temperatures, $T < 50$ K, the mean-free path becomes larger than the average particle separation, $\ell_{mfp} > (d)$, and the LMR is observed to deviate from the mobility. At this point the classical model also breaks down.\(^8\) Another essential feature of the present study is the weak connection between the LMR and the details of the electrical disorder. In the regime where the mobility is small and dominated by phonon scattering it was found that the magnitude of the LMR was essentially identical for several samples possessing different particle sizes and densities. This result indicates that the details of the disorder are not important for generating LMR as long as the mean-free path of the carriers is smaller than the length scale of the system inhomogeneities.

IV. CONCLUSIONS

The results presented here on magnetotransport in MnAs-GaAs composite films reveal that nonsaturating linear magnetoresistance is governed strictly by the average macroscopic carrier mobility. Furthermore, the LMR is complementary to the Hall effect — whereas the LMR is proportional to mobility and independent of carrier density, the Hall voltage is independent of mobility and inversely proportional to the carrier density. For applications, a two-terminal LMR device can be advantageous over a four-terminal Hall-effect device. An important feature of LMR is the insensitivity of the magnetotransport behavior to the degree of the random disorder. These observations provide convincing support for a universal model of a strongly inhomogeneous semiconductor possessing random disorder in the conductivity. This universality renders it applicable to a wide range of materials.
