We present a Green’s function-based framework for modeling the scanning tunneling spectrum from the normal as well as the superconducting state of complex materials where the nature of the tunneling process—i.e., the effect of the tunneling “matrix element,” is properly taken into account. The formalism is applied to the case of optimally doped $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ ($\text{Bi}2212$) high-$T_c$ superconductor using a large tight-binding basis set of electron and hole orbitals. The results show clearly that the spectrum is modified strongly by the effects of the tunneling matrix element and that it is not a simple replica of the local density of states of the Cu $d_{2\to2}$ orbitals with other orbitals playing a key role in shaping the spectra. We show how the spectrum can be decomposed usefully in terms of tunneling “channels” or paths through which the current flows from various orbitals in the system to the scanning tip. Such an analysis reveals symmetry-forbidden and symmetry-enhanced paths between the tip and the cuprate layers. Significant contributions arise from not only the CuO$_2$ layer closest to the tip but also from the second CuO$_2$ layer. The spectrum also contains a longer range background reflecting the nonlocal nature of the underlying Bloch states. In the superconducting state, coherence peaks are found to be dominated by the anomalous components of Green’s function.

DOI: 10.1103/PhysRevB.80.134509  PACS number(s):  68.37.Ef, 71.20.--b, 74.50.+r, 74.72.--h

I. INTRODUCTION

High-resolution scanning tunneling spectroscopy (STS) together with other highly resolved spectroscopies, such as angle-resolved photoemission (ARPES), is making it possible to obtain a comprehensive mapping of the electronic spectrum of the high-temperature superconductors (HTSs) in both real and reciprocal space over a wide range of dopings and temperatures. These studies are providing insight into the rich phase diagrams of the HTSs and are leading thus to a better understanding of the “missing links” for developing a definitive theory of how high superconducting (SC) transition temperatures arise in these unconventional materials. In STS experiments, the focus to date has been on hole doped cuprates, especially on $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ ($\text{Bi}2212$), which has been the subject of an overwhelming amount of experimental work, see, e.g., Refs. 1–6. $\text{Bi}2212$ is a typical cuprate material, which is an antiferromagnetic insulator in the strongly underdoped regime but exhibits a superconducting phase over a wide range of hole doping.

STS can be applied to a substantial part of the doping and temperature spanned phase space of HTS materials. The SC phase is observed around optimal hole doping (OP) while the pseudogap (PG) phase is found within the underdoped regime. As a practical limitation, STS requires a conducting sample but the deeply underdoped regime is insulating and hence unreachable by STS. However, under experimental conditions the samples are not homogeneously doped. Rather, there is a strong spatial variation in doping, which makes observation of a continuum from the PG to the SC phase possible within one sample. Although these spatial variations in STS generally appear irregular, quite recently a more ordered coexistence of PG and SC phases has been observed.7

The physics of the cuprates is dominated by the cuprate layers, which are usually not exposed to the tip of the apparatus. For example, in $\text{Bi}2212$, the quasiparticle tunneling takes place through insulating BiO and SrO layers. The conventional interpretation of the spectra is based on the assumption that the STS spectrum is directly proportional to the local density of states (LDOS) of the CuO$_2$ layer, especially the LDOS of the $d_{2\to2}$ orbitals, thus neglecting the effects of the tunneling process in modifying the spectrum in the presence of the insulating overlayers and multiple orbitals. The motivation for this simplification is an attempt to reduce the quasiparticle structure to few band models, which are amenable to theoretical treatment of strong correlation effects in the presence of superconducting and antiferromag-
nomic order. Notably, there have been attempts to take the effect of the overlayers into account by assuming a “tunneling matrix element” or a “filter function.”

With this background, our recent work on STS (Ref. 10) of Bi2212 provides a significant advance in realistic material-specific modeling of the STS spectrum. We invoke a Green’s function approach where a large number of orbitals is included and all tunneling paths to the tip in the semi-infinite solid are taken into account. We showed clearly that instead of being a simple reflection of LDOS of the Cu $d_{x^2-y^2}$ orbitals, the STS signal represents a very complex mapping of the electronic structure of the system.

In this study we extend our approach by decomposing the tunneling current in terms of regular and anomalous matrix elements of the spectral function in an atomic-orbital basis. As in Ref. 10, we concentrate on Bi2212 as the canonical HTS material. We start by reformulating the well-established methods to model tunneling current in nanostructures into a more transparent form for interpreting tunneling in the superconducting state. Our derivation is based on the conventional Todorov-Pendry (TP) approach, which is closely related to the more common Tersoff-Hamann (TH) method. TP and TH methods both employ a calculation of the LDOS but TP is more naturally written in terms of Green’s functions. We will show, in fact, that TP decomposes into matrix elements of the spectral function, giving very detailed information concerning the origin of various features in the tunneling spectrum. We thus demonstrate how the contribution of different atomic orbitals to the total current can be extracted from the calculations. Our spectral decomposition also naturally distinguishes between the electron and hole nature of the quasiparticles in the superconducting state. In addition, it leads to a multiband generalization of filtering function by Martin et al. and a clarification of selection rules governing tunneling through filtering layers. This information is important, e.g., in determining how a dopant or impurity atom alters the spectrum and how the effect of such a perturbation is seen in real space.

In order to gain a handle on the effects of filtering layers, we derive a consistent form of a filter function through Green’s function manipulations. This rigorous form for the filtering effects is useful for determining the relation between the tunnel current and the LDOS of the CuO$_2$ layers. We show that this relation is nontrivial in that some channels are “first-order forbidden.” Thus our new approach shows that the relation is nontrivial in that some channels are “first-order forbidden.” Thus our new approach shows that the Green’s function in the normal and the superconducting state are derived in Secs. II B and II C, respectively. The Todorov-Pendry equation for the tunneling current is decomposed into regular and anomalous terms to show not only the proper form of the matrix element but also the partial current terms for any chosen orbital in Sec. II D. The formalism is applied to discuss STM topographic maps in Sec. III A and the STS spectrum of Bi2212 in Sec. III B. The spectrum is then analyzed in terms of tunneling matrix elements and partial currents in Sec. III C. Further comments on symmetry analysis are made in Sec. IV A and remarks on electron extraction/injection are made in Sec. IV B. Finally, conclusions are drawn and future applications sketched in Sec. V.

II. DESCRIPTION OF THE MODEL

Our theoretical framework involves three distinct steps. First, we choose a three-dimensional (3D) geometrical model of atoms with a sufficiently large simulation cell with periodic boundary conditions in the horizontal directions to treat a semi-infinite solid surface. Second, we attach a basis set of atomic orbitals to each atom. At this stage, the one-particle Hamiltonian is constructed and the corresponding Green’s function tensor is formed. Third, we apply our Green’s function formalism to evaluate the tunneling current. The technical details of these three steps are outlined in Secs. II A–II C.

A. Sample geometry

We model the Bi2212 sample as a slab of seven layers in which the topmost layer is BiO, followed by layers of SrO, CuO$_2$, Ca, CuO$_2$, SrO, and BiO, as shown in Fig. 1(a). The tunneling computations are based on the $2\sqrt{2} \times 2\sqrt{2}$ real-space supercell consisting of eight primitive surface cells with a total of 120 atoms [see Fig. 1(b)]. The coordinates are
taken from the tetragonal crystal structure of Ref. 15. For STS simulations, the STM tip is modeled as an orbital with an s-wave symmetry at the assumed position of the apex of the tip. This tip is allowed to scan across the substrate for generating the topographic maps such as those in Fig. 5 or held fixed on top of a surface Bi atom for the computed spectra presented for example in Fig. 6.

B. Construction of the uncorrelated normal-state Hamiltonian

In order to construct a realistic framework capable of describing the tunneling spectrum of the normal as well as the superconducting state of the cuprates, we start with the normal-state Hamiltonian for the semi-infinite solid in the form

\[ \hat{H}_1 = \sum_{\alpha \beta \sigma} [E_{\alpha} c^\dagger_{\alpha \sigma} c_{\alpha \sigma} + V_{\alpha \beta} c^\dagger_{\alpha \sigma} c^\dagger_{\beta \sigma}], \]

which describes a system of tight-binding orbitals created (or annihilated) via the real-space operators \( c^\dagger_{\alpha \sigma} \) (or \( c_{\alpha \sigma} \)). Here \( \alpha \) is a composite index denoting both the type of orbital (e.g., \( Cu d_{z^2-r^2} \)) and the site on which this orbital is placed, and \( \sigma \) is the spin index. \( E_{\alpha} \) is the on-site energy of the \( \alpha \)th orbital. \( \alpha \) and \( \beta \) orbitals interact with each other through the potential \( V_{\alpha \beta} \) to create the energy eigenstates of the entire system.

The specific electron and hole orbital sets used for various atoms are \( s, p_x, p_y, p_z \) for Bi, Ca, and O; \( s \) for Sr; and \( 4s, d_{3z^2-r^2}, d_{xy}, d_{xz}, d_{yz} \) for Cu atoms. This yields 58 electron or hole orbitals in a primitive cell and a total of \( 2 \times 464 \) orbitals in the \( 2\sqrt{2} \times 2\sqrt{2} \) simulation supercell. The number of \( \mathbf{k} \) points used in the computations depends on whether we do band calculations or solve the Green’s function. For band calculations, we use a dense set of \( \mathbf{k} \) values to produce smooth bands for directions \( \Gamma \rightarrow M \rightarrow X \rightarrow \Gamma \) as seen, for example, in Fig. 2. In the case of Green’s function calculations, we use \( N_k = 256 \) \( \mathbf{k} \) points for the supercell Brillouin zone. This corresponds to \( 8 \times 256 = 2048 \) \( \mathbf{k} \) points for a primitive cell.

The Slater-Koster formalism\(^{16-18}\) is used to fix the angular dependence of the tight-binding overlap integrals. The on-site energies and the prefactors are fitted to the local-density approximation (LDA) band structure of Bi2212 that underlies, for example, the extensive angle-resolved photoemission spectrum computations of Refs.\(^{19-24}\). In Table I, we show the specific values of the \( u_{\alpha \beta \gamma \delta} \) prefactors used for computing the Slater-Koster hopping integrals. Notably, we have shifted the bottom of the BiO conduction band to agree with experiments, which do not observe the Bi bands at least within 1 eV above the Fermi level. This choice is also supported by calculations of Ref.\(^ {25}\), which show the sensitivity of the position of the Bi band with respect to impurities and doping.

The absence of the bottom of the BiO band in the STS spectra may also be due to a voltage gradient across the insulating filter layers (BiO and SrO layers) when applying a bias voltage between the tip and the sample. If so, the absolute value of the voltage within these layers is less than the bias voltage \( V_b \) and thus the apparatus would need to apply a bias which would be significantly larger than \( V_b \) to locally see states that are strictly at \( E_F + eV_b \).

The tight-binding parameters of the normal-state Hamiltonian of Eq. (1) produce the detailed band structure of Bi2212 shown in Fig. 2. While the tight-binding band structure is in reasonable agreement with the LDA band structure of Ref.\(^ {25}\), in order to carry out spectroscopic computations, one must additionally make sure that the underlying wave functions are described correctly including their symmetries. Our procedure based on the use of Koster-Slater matrix elements not only fits the band structures but the symmetries and phases of the associated wave functions are also described correctly.

Figures 2(a) and 2(b) show the normal-state tight-binding band structure based on our 58 orbital Hamiltonian of Eq. (1). The main cuprate bands, with predominantly \( Cu d_{z^2-r^2} \) character, are seen in panels (a) and (b) to follow the corre-
TABLE I. Slater-Koster prefactors, \( v_{\alpha \beta \sigma} \), and on-site energies \( \varepsilon_{\alpha} \). The \( v_{\alpha \beta \sigma} \) are used to construct the Hamiltonian overlap matrix elements \( V_{\alpha \beta} \) as described in Ref. 16.

In our tight-binding modeling, we have adjusted the positions and bilayer splitting of the two van Hove singularities (VHSs) to approximately match the experimental photoemission and STS findings for the OP region with hole concentration \( p = 0.16 \) (Refs. 26 and 27). In addition to Cu \( d_{z^2-\gamma^2} \), Cu \( d_{\gamma^2} \) is seen in panels (b) and (d) to give a significant spectral weight to this band, especially at energies below the Fermi level. The complicated “spaghetti” region has large contributions from the \( d_{z^2} \) of Cu and horizontal \( p_x \) orbitals of the oxygen within the cuprate layer as well as the vertical \( p_y \) orbital of the apical oxygen. Concerning the filter layers, the bottom of the BiO-like conduction band (or bismuth pocket) along the \( M(\pi, 0) \) direction carries the character of the horizontal \( p \) orbitals of the surface oxygens O(Bi) [see Fig. 2(a)].

In tunneling calculations, we directly evaluate the Green’s function instead of diagonalizing the Hamiltonian. For this purpose, the normal-state Green’s function is solved first by starting from the orbital matrix elements of the Green’s function,

\[
\hat{G}_{\alpha \beta} = \frac{\delta_{\alpha \beta}}{\varepsilon - \varepsilon_{\alpha} - \Sigma_{\alpha}^{\pi}(\varepsilon)},
\]

where \( \varepsilon_{\alpha} \) is the on-site energy of the orbital \( \alpha \). At this point, a diagonal self-energy \( \Sigma_{\alpha}^{\pi} = \Sigma_{\alpha}^{\pi} + i\Sigma_{\alpha}^{\sigma} \) can be included straightforwardly. The simplest self-energy is a constant broadening of the states in the form of a convergence factor \( \Sigma_{\alpha}^{\pi} = \mp i\eta \). Appendix A [Eq. (A2)] presents a more general self-energy which we use to model electron-boson coupling.

The total Green’s function \( G \) is constructed by solving Dyson’s equation

\[
G = g + gVG,
\]

where \( V_{\alpha \beta} \) are the off-diagonal overlap integrals of Eq. (1) Dyson’s equation is exactly solved using the method described in Ref. 28, which is suitable for tunneling calculations.

C. Pairing interaction and the superconducting state

Hamiltonian

Superconductivity is included by adding a pairing interaction term \( \Delta \) in the Hamiltonian of Eq. (1) as follows:

\[
\hat{H} = \hat{H}_1 + \sum_{\alpha \beta \sigma} \left[ \Delta_{\alpha \beta - \sigma} F_{\sigma \sigma} \right] + \Delta_{\alpha \beta - \sigma} F_{\sigma \sigma} \Delta_{\alpha \beta - \sigma},
\]

A gap parameter value of \( |\Delta| = 0.045 \) eV is chosen to model a typical experimental spectrum for the illustrative purposes of this study. We take \( \Delta \) to be nonzero only between \( d_{z^2-\gamma^2} \) orbitals of the nearest-neighbor (NN) Cu atoms and to possess a \( d \)-wave form, i.e., \( \Delta_{d_{z^2-\gamma^2}} = +|\Delta| \) and \( \Delta_{d_{z^2-\gamma^2}} = -|\Delta| \), where \( d \) denotes the \( d_{z^2-\gamma^2} \) orbital at a chosen site and \( d \pm x/y \) the \( d_{x^2-y^2} \) orbital of the neighboring Cu atom in \( x/y \) direction. In momentum space, the corresponding \( \Delta \) is given by

\[
\Delta_k = \frac{\Delta}{2} \cos k_x a - \cos k_y a,
\]

where \( a \) is the in-plane lattice constant. The pairing interaction of Eq. (3) allows electrons of opposite spins to combine to produce superconducting pairs such that the resulting superconducting gap is zero along the nodal directions \( k_x = \pm k_y \) and is maximum along the antinodal directions. This choice of pairing interaction follows, e.g., the one-band formalism given in Ref. 30.

For treating the superconducting case, we employ the tensor (Nambu-Gorkov) Green’s function \( \mathcal{G} \) (see Ref. 31) with the corresponding Dyson’s equation,

\[
\mathcal{G} = \mathcal{G}_e + \mathcal{G} \mathcal{V} \mathcal{G}_e^0,
\]

where

\[
\mathcal{G} = \begin{pmatrix} G_e & F_e \\ F_e & G_h \end{pmatrix} \quad \text{and} \quad \mathcal{V} = \begin{pmatrix} 0 & \Delta \\ \Delta^\dagger & 0 \end{pmatrix},
\]

where \( G_e \) and \( G_h \) denote the Green’s functions for the electrons and holes, respectively.

The normal-state electron Green function \( G_e \) can be used to derive the hole Green function \( G_h \). It can be shown by, e.g., the equation of motion method that
SPECTRAL DECOMPOSITION AND MATRIX ELEMENT...

\[ G_{h,\alpha}^\pm(\epsilon) = - G_{c,\beta}^{\pm}(\epsilon - \epsilon). \]

It is straightforwardly shown then that

\[ G_c = G_c^0 + F\Delta G_c^0, \]

\[ F = G_c\Delta G_c^0. \]  

(6)

The quasiparticle Green’s function projected onto electron degrees of freedom is then written in the form

\[ G_c = G_c^0 + G_c\Sigma_{\text{BCS}}^* G_c^0, \]

(7)

where \(\Sigma_{\text{BCS}} = \Delta G_c^0\Delta.\)

We also need the self-energy term \(\Sigma_{\alpha}^h\) for holes. Since the transformation from electron to holes follows that of the Green’s function, we obtain the general form

\[ \Sigma_{\alpha}^h(\epsilon) = - \Sigma_{\alpha}^c(-\epsilon) = - \Sigma_{\alpha}^c(\epsilon) + i\Sigma_{\alpha}^c(\epsilon). \]

In our particular case, we use a self-energy with an odd real part and an even imaginary part as discussed in Appendix A [see Eq. (A2)]. Our self-energy is thus invariant under electron-hole transformation.

Figures 2(e) and 2(f) show the modifications of the normal-state band structure from the introduction of the pairing interaction. Only the region within ±500 meV of the Fermi level is shown in panel (e), as the remainder of the bands are unchanged from the normal-state results of panels (a) and (b). The superconducting state dispersion in panels (e) and (f) clearly displays a \(d\)-wave gap with a maximum in the antinodal region near the \(M\) point and zero gap along the nodal direction near (\(\pi/2, \pi/2\)). Note that both bonding and antibonding VHSs possess gaps of similar magnitude. Figure 2(e) also shows the relative electron/hole character of the quasiparticles. As expected, the quasiparticles are very distinctly either electronlike or hololeike almost everywhere except within a very narrow energy range at the top and bottom of the SC gap. Figure 3 further shows that mixing of the electron and hole features gives rise to coherence peaks in the LDOS of Cu \(d_{\text{z}^2-\text{r}^2}\) and to a lesser extent in the LDOS of Cu \(d_{\text{z}^2}\). The effects of electron-hole mixing are however most pronounced in the anomalous matrix element of the quasiparticle Green’s function (inset of Figs. 3 and 4). In fact, the off-diagonal matrix element between an up-spin \(d_{\text{z}^2-\text{r}^2}\) electron orbital and a down-spin \(d_{\text{z}^2-\text{r}^2}\) hole orbital of two neighboring Cu atoms gives the most important term in the anomalous part of the Green’s function. This term has \(d\)-wave symmetry, which manifests itself as a change in sign each time we make a rotation of \(\pi\) around the central Cu site.

In addition to the coherence peaks, the anomalous density matrix, which in view of electron-hole symmetry inherits features from the VHSs in the regular part of the density matrix, is reflected on both sides of the Fermi energy. Additionally, strong hybridization between up-spin Cu \(d_{\text{z}^2-\text{r}^2}\) electron orbitals and down-spin orbitals of O \(p_x\) holes (and vice versa) takes place as shown in Fig. 4. This term is comparable in strength to the Cu \(d-Cu\) terms and changes sign in rotations of \(\pi\) for reasons explained in the special case (3) of the following paragraph. Figure 4 also shows a small on-site contribution from the up-spin electron and down-spin hole of the \(p_x\) orbital on the oxygen between two neighboring Cu atoms. It is notable that these matrix elements strictly follow the \(d\)-wave symmetry in rotations around the central Cu atom.

These transformation properties follow consistently from Eq. (6). Let us, for example, look at the equation in the \(x\) direction: 

\[ F_{\alpha\beta} = G_{e,\alpha}(\Delta d_{\text{z}^2-\text{r}^2} G_{h,\beta}(\Delta d_{\text{z}^2-\text{r}^2}) \]

where \(d\) is a shorthand notation for \(d_{\text{z}^2-\text{r}^2}\) of a chosen Cu atom and \(d \pm x\) stands for the \(d_{\text{z}^2-\text{r}^2}\) orbital of the neighboring Cu atom in the positive/negative \(x\) direction and consider several specific cases as follows.

(1) For \(\alpha = d\) and \(\beta = d \pm x\), both \(G_{e,\alpha}\) and \(G_{h,\beta}\) are on-site matrix elements and thus their sign remains invariant when changing from one Cu to another. Hence the term \(\Delta d_{\text{z}^2-\text{r}^2}\) is decisive and the sign can change only in going from \(x\) to \(y\) direction.

FIG. 4. (Color online) Main: matrix elements of the anomalous Green’s function for on-site \(p_x\) orbital of an intermediate oxygen atom (green lines), \(d_{\text{z}^2-\text{r}^2}\) orbitals of two neighboring Cu atoms (red lines), and between Cu \(d_{\text{z}^2-\text{r}^2}\) and a \(p_x\) orbital of a neighboring oxygen (black lines). Inset: the directional dependence of the sign of the off-diagonal element \(F_{dp}\). For details see special case (3) in the text.

FIG. 3. (Color online) Main: LDOS (or the diagonal elements \(\rho_{\alpha\alpha}\) of the density matrix; see Appendix B for details) of \(d_{\text{z}^2-\text{r}^2}\) (green) and \(d_{\text{z}^2}\) (blue) orbitals of Cu. [Note \(d_{\text{z}^2}\) curve is scaled up by a factor of 4.5 to compare the shapes of the two LDOSs.] Oscillations at high positive or negative energies (above ±0.5 eV) are artifacts due to the use of a sparse mesh of \(k\) points in the computation. Inset: Anomalous density matrix term \(\rho_{\alpha\beta}^a\) discussed in Appendix B, where \(\alpha\) and \(\beta\) denote \(d_{\text{z}^2-\text{r}^2}\) orbitals of two neighboring Cu atoms.
(2) For $\alpha = \beta = O p_{\alpha}$, we have to first look at the term $G_{p, p'} G_{h}(d, x)p_{\alpha}$. Since the relative phases of the off-diagonal matrix elements of the Green’s function are proportional to the sign of the overlap of the two orbitals, it is straightforward to see from the signs of the lobes of the $d$ and $p$ orbitals that this product is invariant in change in direction as well as in going from $x$ to $y$. Therefore, $\Delta_{d, h(x)}$ again gives the $d$-wave symmetry of these terms.

(3) For $\alpha = d$ and $\beta = O p_{\alpha}$, $G_{e, a}$ is diagonal and thus invariant. Considering the overlaps, one sees that

$$G_{h, (d-x)} G_{h, (d-x)} = G_{h, (d+x)} G_{h, (d+x)}$$

and

$$G_{h, (d+y)} G_{h, (d+y)} = -G_{h, (d+y)} G_{h, (d+y)}$$

But, since $\Delta_{d, h(x)} = \Delta_{d, h(y)}$,

$$F_{dp, (x)} = F_{dp, (y)} = F_{dp, (x)} = F_{dp, (y)},$$

as shown in the inset of Fig. 4.

Equation (B5) of Appendix B shows that $F_{a, b}$ is given in terms of the retarded electron Green’s function or propagator $G_{e, p}$.

Recall that we introduced superconductivity in Hamiltonian (C) only on the Cu $d_{z^2-r^2}$ orbitals. Thus we see that within our model the strong Cu-O hybridization automatically induces pairing on the oxygen orbitals. This pairing is analogous to the concept of Zhang-Rice singlets (ZRSs) in the low doping limit, where pair states

$$|d_{z^2-r^2} \uparrow \rangle \langle d_{z^2-r^2} \uparrow | = |d_{z^2-r^2} \downarrow \rangle \langle d_{z^2-r^2} \downarrow |$$

are formed. Note, however, that ZRS is a concept related to doping levels in the “normal” phase and is not directly concerned with superconductivity. Nevertheless, the preceding considerations indicate that our model is in accord with the ZRS scenario of the normal state.

D. Green’s function formulation of tunneling current

We turn now to consider the formulation of the tunneling current. For this purpose, we apply the conventional form of the Todorov-Pendry expression for the differential conductance $\sigma$ between orbitals of the tip ($t, t'$) and the sample ($s, s'$), which in our case is straightforwardly shown to yield

$$\sigma = \frac{dI}{dV} = \frac{2\pi e^2}{h} \sum_{t', s'} \rho_{s't'}(E_F) V_{t't'} \rho_{s's'}(E_F + eV) V_{s's'},$$

where the density matrix

$$\rho_{s's'} = -\frac{1}{\pi} \text{Im} [G_{s's'}^+] = \frac{1}{2\pi i} \left( G_{s's'}^+ - G_{s's'}^+ \right)$$

is given in terms of the retarded electron Green’s function or propagator $G_{e, a}^+$. Eq. (8) differs from the more commonly used Tersoff-Hamann approach in that it takes into account the details of the symmetry of the tip orbitals and how these orbitals overlap with the surface orbitals.

Since electrons are not eigen particles in the presence of the pairing term, Dyson’s equation needs to be applied to the Green’s function tensor,

$$\tilde{G} = G^+ + G^+(\Sigma^--\Sigma^+)G^- = G^+ - 2i\Sigma^+ G^- G^+.$$

After extracting the electron part from Eq. (10) and applying Eq. (9), the spectral function can be written as

$$\rho_{s't'} = \frac{1}{\pi} \sum_{\alpha} \left( G_{s'a}^+ G_{a's'} - G_{s'a}^+ G_{a's'}^+ \right).$$

Using Eq. (11), the tunneling current of Eq. (8) can be recast into the form

$$\sigma = \sum_{\alpha} T_{t\alpha},$$

where

$$T_{t\alpha} = \frac{2e^2}{h} \sum_{s's'} \rho_{s's'}(E_F) V_{t's'} (G_{s'a}^+ G_{a's'} - G_{s'a}^+ G_{a's'}^+) V_{s's'}$$

and the Green’s function and the self-energy are evaluated at the energy $E = E_F + eV$. Equations (12) and (13) are an extension of the Landauer-Büttiker formula for tunneling across nanostructures (see, e.g., Ref. 34) and represent a reformulation of Refs. 35 and 36. By comparing Eqs. (11) and (13), we see that if the tip makes contact only with a single surface-atom orbital, e.g., a Bi $p_z$ orbital, then the tunneling current is directly proportional to the LDOS of that orbital. In particular, the tunneling current bears in general no such simple relationship to the quantity of most interest, namely, the LDOS on the CuO$_2$ plane. Obviously, the tunneling formalism of Eq. (13) must be further elaborated in order to find the relation between the interesting LDOSs and the tunneling spectrum.

Tunneling channels, filter function, and tunneling matrix element

The experimental STM spectra in the cuprates have to date been mostly compared to the electronic LDOS of the superconducting cuprate layer, especially the LDOS of the Cu $d_{z^2-r^2}$ orbital. The discrepancies between the spectra and the LDOS are then ascribed to tunneling matrix elements or “filtering functions.” 28 The former refers to the general problem of modeling spectroscopies, where the signal is distorted by the spectroscopic process and may even vanish due to the presence of selection rules. The latter term refers to how the states of electrons (or quasiparticles) from the initial state within the superconducting layers are modified when traveling through the oxide overlayers before reaching the tip.

Equation (13) above accounts fully for the tunneling process and it can be reformulated to reveal, for example, the filtering effect more clearly. For this purpose, it is convenient to the denote various orbitals as follows: $s$ and $s'$ for the orbitals of the sample surface, which overlap with the tip orbital $t$; $f$ and $f'$ for the orbitals of the filter layers, BiO and SrO; $c$
and $c'$ for orbitals in the cuprate layer; and $\alpha$ for any orbital that is singled out, which in our case usually will be an orbital in the cuprate layer. Denoting the Green’s function for the filter layers decoupled from the rest of the system by $G_{sf}$ and the matrix elements within the cuprate layer in the coupled system by $G_{ca}$, application of Dyson’s equation to $G_{sf}$ yields

$$G_{sf} = G_{sf}^0 V_{fc} G_{ca} + F_{sf}^0 V_{fc} F_{ca}^+.$$  

Hence, Eq. (13) can be written as

$$T_{t\alpha} = -\frac{2\pi e^2}{\hbar} \sum_{\alpha'c'} \rho_{t\alpha'}(E_F) M_{t\alpha'}(G_{ca}^{\alpha\alpha'} G_{ac}^{\alpha'} + F_{ca}^{\alpha\alpha'} F_{ac}^{\alpha'}) M_{t\alpha'}^\dagger,$$  

(14)

where

$$M_{t\alpha} = V_{tc} G_{cf} V_{fc},$$  

(15)

which gives the filtering amplitude between the cuprate layer and the tip, and constitutes a multiband generalization of filtering function of Ref. 8. Similarly, the matrix element of the density-of-states operator $\rho_{t\alpha'}$ within the cuprate plane can be recovered in terms of the spectral function,

$$\sigma = \frac{2\pi e^2}{\hbar} \sum_{\alpha'c'} \rho_{t\alpha'}(E_F) M_{t\alpha'} \rho_{c'\alpha'}(E_F + eV) M_{t\alpha'}^\dagger.$$  

(16)

Equations (14)–(16) show a number of interesting aspects of the tunneling process as follows.

1. Since applying the filtering matrix element $M_{t\alpha}$, which describes the effect of the BiO and SrO overlayers, involves $M$ and $M^\dagger$, interference effects will occur between various paths to the tip from the cuprate layers through the filter layer.
2. The partial current terms in Eq. (16) under the summation are proportional to elements of the density matrix confined to the cuprate layer. Only orbitals with a notable overlap with the $p_z$ orbital of the apical oxygen on the SrO layer will give a significant contribution to the total current;
3. The partial elements of the spectral function

$$\rho_{\alpha'\alpha} = -\frac{1}{\pi} \left( G_{ca}^{\alpha\alpha'} G_{ac}^{\alpha'} + F_{ca}^{\alpha\alpha'} F_{ac}^{\alpha'} \right)$$  

(17)

extracted from Eq. (14) show which orbitals $\alpha$ contribute to the chosen element of the density matrix $\rho_{c'\alpha'}$. Furthermore, the current contribution $T_{t\alpha}$ between the tip can be divided into regular and anomalous terms $T_{t\alpha}^R$ and $T_{t\alpha}^A$, respectively.

Since the filter layers are insulating at low energies, these layers will give little structure to the spectrum at low bias voltages so that the structure of the spectrum is mainly controlled by the matrix elements $\rho_{c'\alpha'}$ and in this sense the spectrum is a filtered mapping of the LDOS of the cuprate orbitals. We will show however that the Cu $d_{z^2}$ orbitals right below the tip do not enter the spectrum through Eq. (16) since their overlap with the relevant orbitals of the SrO layer is zero. Instead, Cu $d_{z}$ has a large overlap with $p_z$ of the apical oxygen and hence these orbitals of the Cu atoms play a dominant role in the tunneling spectrum.

The detailed contribution of any specific orbital $\alpha$ can be extracted from Eq. (14). The regular and anomalous matrix elements of the spectral function, $G_{ca}^{\alpha\alpha'} G_{ac}^{\alpha'}$ and $F_{ca}^{\alpha\alpha'} F_{ac}^{\alpha'}$, describe propagation of electrons or holes within the cuprate layer from orbital $\alpha$ to the orbitals $c$ and $c'$. The latter orbitals act as “gates” between the cuprate layer and the filter layer. For example, if $\alpha$ is $d_{z^2}$ of a Cu atom and $c$ and $c'$ are $d_{z}$ orbitals, which strongly overlap with the filter layer, the matrix element filtered by $M$ and $M^\dagger$ gives the contribution of a specific $d_{z^2}$ orbital to the total tunneling spectrum. Note that in the superconducting state the anomalous matrix elements of the spectral function must also be considered. $F_{c\alpha'}(\tau)$ involves the creation of an electron with spin up coupled to the annihilation of a hole with spin down given by $\langle c_{\beta}^{\dagger}(\tau)c_{\alpha}(0) \rangle$ and thus describes the formation and breakup of Cooper pairs as shown in Appendix B. The decomposition of Eqs. (14)–(16) are, in fact, a generalization of the tunneling channel approach to transport through one-molecule electronic components and STM of adsorbate molecules. In the present context, the “tunneling path” analysis gives us the “origin” of the signal since $G_{ca}^{\alpha\alpha'} G_{ac}^{\alpha'}$ gives the probability of propagation between orbitals $\alpha$ and $c$.

**III. RESULTS**

**A. Topographic maps**

We discuss first the topographic STM map after Ref. 4. (b) The computed corrugation of two STM line scans and (c) theoretically predicted topographic map. The two paths are shown in (c) by arrows.

![Image](b0805_f5.png)  

**FIG. 5.** (Color online) (a) Typical experimental topographical STM map after Ref. 4. (b) The computed corrugation of two STM line scans and (c) theoretically predicted topographic map. The two paths are shown in (c) by arrows.

The Bi atoms are seen as bright spots while the surface oxygen is dark due to very low current coming through these surface atoms. We will see in connection with the analysis of the tunneling channels below that the apical oxygen act as the primary gate for passing electrons from the CuO$_2$ layers up to the surface BiO layer. Accordingly, the Bi...
The apical oxygen as discussed below in connection with Fig. 6(b) is generally believed to be the result of the coupling of electronic degrees of freedom to a collective mode (Refs. 9, 44, and 45). Figure 6(b) shows that the peak-dip-hump feature can be described by our simple self-energy correction discussed in Appendix A. This point however requires further study, including an analysis of how this feature evolves with doping.

C. Selection rules

The filter function $M_\alpha$ controls selection rules dictated by matching of the symmetry properties of the cuprate layer, filter layers, and the tip. A closer examination of $M_\alpha$ reveals that strong tunneling through the apical oxygen layer is associated with a matching of the symmetry of the cuprate layer wave function to that of the apical O $p_z$. The key is the relative symmetry of the wave functions with respect to the axis of tunneling: An “odd” wave function, e.g., the Cu $d_{2z}$ has zero overlap with an “even” wave function such as O $p_z$. In contrast, two orbitals with the same symmetry couple more strongly. Accordingly, the $p_z$ of the apical oxygen and the Cu $d_{2z}$ possess large overlap while Cu $d_{2z}$ has zero overlap with any $s$ or $p$ orbital of the apical oxygen. This is the reason that direct tunneling is forbidden between Cu $d_{2z}$ and the $s$-wave symmetric tip through the filter layer. Hence, $M_\alpha$ functions here are consistent with the filter function of Ref. 8. Similarly, coupling between an $s$-wave tip and the $p_x$ and $p_y$ orbitals of the Bi atom lying directly below the tip is forbidden. Therefore, within the filter layer, the main “vertical” overlap is between the $p_z$ orbitals of Bi and apical oxygen, and these orbitals indeed are found to provide the main channel through the filter layers as depicted in Fig. 7(a). We find additional relatively small contributions from the on-site Bi $s$ orbital and $p$ orbitals of the surrounding Bi and O(Bi) atoms but such “background” contributions to the current do not seem to be dominated by any particular channel.

Figure 7(b) illustrates another example of a symmetry-forbidden tunneling path, where the tip is centered between two surface Bi’s, i.e., on the top of an oxygen of the cuprate layer. Since we assume an $s$-wave tip with negative hopping

![Image](http://example.com/image1.png)

**FIG. 6.** (Color online) (a) A typical experimental tunneling spectrum (red line) from Bi2212 (after Ref. 2) is compared with the calculated spectrum (black). The green curve shows the LDOS of the Cu $d_{2z-2}$ orbitals and the self-energy from the convolution of a Debye-type phonon spectrum and the LDOS of Cu $d_{2z-2}$ [Eq. (A1)] as discussed in Appendix A.

![Image](http://example.com/image2.png)

**FIG. 7.** (Color online) (a) Dominant tunneling channel from the cuprate layer, from Cu $d_{2z}$ orbitals through the neighboring Cu $d_z$ to Bi $p_x$ to the tip. (b) An oxygen atom in the cuprate layer is invisible to a STM tip right above when the paths through Cu1 and Cu2 interfere destructively.

B. Tunneling spectra

Figure 6(a) compares a typical experimental (red/light line) STS spectrum to the calculated one (black/dark line). The overall agreement between theory and experiment is seen to be good, although the VHSs are seen as separate structures in the calculated curve. The agreement also extends to the low-energy region shown in Fig. 6(b), where the width and positions of the coherence peaks is reproduced reasonably well. The tendency for increasing intensity toward negative bias is seen in both measurements and computations. This is in sharp contrast to the shape of the LDOS of Cu $d_{2z-2}$ orbitals (green curve). As emphasized in Ref. 10, this remarkable asymmetry of the spectrum between positive and negative bias voltages reflects the opening up of channels other than Cu $d_{2z-2}$, especially of Cu $d_z$, as one goes to high negative bias. This asymmetry thus appears naturally within our conventional picture and cannot be taken to be a hallmark of strong correlation effects as has been thought to be the case.
integrals to the nearby Bi atoms, when we follow either path up to the Cu \(d_{z^2-r^2}\) orbitals, the signs of the hopping integrals are identical. However, the O \(p_z\) orbital between the two Cu atoms changes sign from one Cu to the other. This gives the two paths from O \(p_z\) to the s-wave tip an opposite phase leading to destructive interference between the paths, making the O atom invisible. However, if the s-wave tip is replaced by one with, e.g., \(p_x\) symmetry, the oxygen would become visible and a weaker signal would appear from the neighboring \(d_{z^2-r^2}\) orbitals. Experimentally, this could be accomplished by functionalizing the tip by attaching a suitable molecule to the tip. A similar procedure has been used to obtain a contrast inversion for CO molecules adsorbed on a Cu surface.\(^{46,47}\)

### D. Tunneling channels

The origin of the current from the cuprate layer can be understood by inspecting the individual terms of Eq. (17), which we refer to as “tunneling channels,” i.e., from the regular and anomalous elements \(G_{r,c}^{x,x} \sum_{\alpha} G_{\alpha c}^{x,x}\), and \(F_{r,c}^{x,x} \sum_{\alpha} F_{\alpha c}^{x,x}\), of the Green’s function. [Although tunneling channels are a normal-state property, the anomalous matrix elements play an important role in generating the coherence peaks and thus are relevant more generally.] For simplicity, we assume that the tip is right above a Bi atom. The dominant element of the filter function \(M_{rl}\) is then between the tip orbital and the \(d_{z^2}\) orbital of the upper layer Cu atom lying beneath the surface Bi atom, so we take \(c' = c = \text{Cu} d_{z^2}\) in results shown in Figs. 8 and 9. Figure 8 shows the relative contributions of the regular and anomalous matrix elements. The near Fermi energy current is primarily associated with the \(d_{z^2-r^2}\) matrix elements. While the regular matrix elements of Cu \(d_{z^2-r^2}\) are almost solely responsible for the spectrum at energies around the VHSs, the anomalous elements determine the features around the gap region, especially the coherence peaks. Figure 8 shows that coherence peaks are inherited from the anomalous and not the regular part of the Green’s function, and reflect physically the effects of nonconservation of the number of electrons near the gap region.

In Fig. 9, the current of \(d_{z^2-r^2}\) character is further broken down into contributions from various neighbors of the central Cu atom of the first and second CuO\(_2\) layer away from the free surface. We see in panel (a) that the upper CuO\(_2\) layer is more important than the lower one but that the upper layer is by no means dominant. It seems that the coupling between the tip and the lower layer is strengthened via the relatively large overlap between the \(d_{z^2}\) orbitals of the central Cu atoms of the two layers, which opens an important interlayer channel. The \(d_{z^2-r^2}\) orbitals of the two layers mix not only to induce the well-known bilayer splitting in Bi2212 but also play a significant role in the flow of current to the tip from the lower cuprate layer.

It can be seen from Fig. 9(a) that the \(d_{z^2-r^2}\) orbitals of the four nearest-neighbor Cu atoms of the central Cu give a significant contribution to the total spectrum but that this amounts to only about one third of the contribution from all \(d_{z^2-r^2}\) terms from the upper layer. Due to the nonlocal nature of the Bloch states within the cuprate layers, it is clear then that the total signal involves long-range contributions and attributing the spectrum merely to the four nearest-neighbor Cu atoms provides only a rough approximation.

Anomalous contributions are considered in Fig. 9(b). Here, the upper and lower layers give an almost equally large contribution, indicating that coherence peaks also are not all that local in character. Notably, we find a finite on-site anomalous contribution of \(d_{z^2-r^2}\) even though the regular term is zero. This can be understood with reference to Eq. (6). Consider the term

\[ F_{r,d} = G_{r,c}^{0} \Delta_{(d+x)} G_{h,d d}, \]

where \(d\) is shorthand for \(d_{z^2-r^2}\) of the central Cu and \(d+x_i\) is \(d_{z^2-r^2}\) of the neighboring Cu in either x or y direction. Clearly, \(G_{r,c}^{0} \Delta_{(d+x)}\) transforms under rotations of \(\frac{\pi}{2}\) in the same way as \(\Delta_{(d+x)}\) and since \(G_{h,d d}\) is an on-site term, the combination is invariant. Hence the four terms in the sum over the neighbors are equal, yielding a nonzero onsite term.

We emphasize that the anomalous contribution of the four neighboring Cu atoms is quite small. Let us consider the term

\[ F_{r,d} = G_{r,c}^{0} \Delta_{(d+x)} G_{h,d d}, \]
The selection rules can be formalized using group theoretical arguments related to the filtering function. For example, in order to explain the dominance of the \(d_{x^2-y^2}\) orbitals of the four neighboring \(d_{x^2-y^2}\) orbitals of the four neighboring Cu atoms, considering representations of the two-dimensional \(C_{4v}\) group, the \(d\) orbitals \(|d_{x^2-y^2},i\rangle\) of the site \(i\) participate in eigenfunctions of the system as a linear combination

\[
\sum_i e^{-i\mathbf{k}\cdot\mathbf{R}_i}|d_{x^2-y^2},i\rangle.
\]

This combination of the four neighboring orbitals at \((0, \pi)\) and \((\pm \pi, 0)\) belongs to the same representation of \(C_{4v}\) as the 4s and \(d_{x^2-y^2}\) orbitals of the central Cu atom (see Fig. 10), as well as the \(p_z\) orbitals of the apical oxygen and the surface Bi atom. At this \(k\) point, the phase difference between the lattice sites causes all the \(d\)-orbital lobes pointing toward the central atom to have the same sign. Hence, this combination yields a large off-diagonal element overlap with the surface \(p_z\) orbital and a dominant tunneling contribution around the gap. Similar arguments can be applied to understand contributions from other farther out atoms. An example was given in Fig. 7(b) above where the position of the tip and the symmetry of the relevant orbital strongly influence the visibility of an atom.

B. Electron extraction/injection

We have concentrated in this study on the large hole doping regime of the cuprates layer, we have introduced the concept of tunneling paths through Eq. (14), which implies that each path begins or ends on a particular atomic orbital. This nonintuitive concept requires some comment. In reality, the current flows through the sample with each electron ejected to the tip being replaced by an electron from a distant counterelectrode. For a simple system, such as a nanostructure, nonequilibrium Green’s function formalism with two “leads” closing a current circuit have been invoked (see, e.g., Ref. 34). TH or TP approach, on the other hand, assumes that the current is composed of a series of tunneling events and that the replacement of electrons at the counterelectrode has a negligible effect on the tunneling process. Since the current in STS is on the order of 10–100 pA, there is only about one electron each 1–10 ns which flows across the sample, justifying the assumptions underlying TH/TP approach. Both TH and TP are based on calculating individual tunneling events in a low-energy electron diffraction-like formalism. Due to the finite \(\Sigma''\), an electron created on a particular atom will have only a finite probability of escaping to the tunneling tip and Eq. (14) shows how to add up the contribution of all these tunneling processes in terms of the equilibrium LDOS of the sample.
fact that we have obtained good overall agreement between our computations and the measurements, especially with respect to the pronounced asymmetry of the spectrum between positive and negative bias voltages, indicates that this remarkable asymmetry can be understood more or less within our conventional picture without the need for invoking exotic mechanisms. At lower dopings, strong correlation effects including the possible presence of competing orders or inhomogeneous electronic states (nanoscale phase separation) would need to be taken into account. However, the present framework can be extended fairly straightforwardly through the addition of Hubbard terms in the Hamiltonian to provide a viable scheme for investigating the tunneling response throughout the phase diagram of the cuprates and other complex materials, including the modeling of effects of impurities and dopant atoms in the system.

**ACKNOWLEDGMENTS**

This work is supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences under Contract No. DE-FG02-07ER46352 and benefited from the allocation of supercomputer time at NERSC, Northeastern University’s Advanced Scientific Computation Center (ASCC), and the Institute of Advanced Computing, Tampere. RSM’s work has been partially funded by the Marie Curie Grant PIIF-GA-2008-220790 SOQCS. I.S. would like to thank the Wihuri Foundation for financial support. Conversations with Jose Lorenzana and Matti Lindroos are gratefully acknowledged.

**APPENDIX A: BOSON-ELECTRON COUPLING**

In the vicinity of the Fermi energy, dispersion anomalies are found in ARPES spectra arising from coupling of electronic degrees of freedom to phonons and/or magnetic modes, often giving the appearance of a peak-dip-hump feature.44 These boson-electron couplings also strongly affect the STS spectrum;45 This appendix discusses a model self-energy for describing such anomalies.

A significant contribution to the electron-phonon coupling is associated with modulation of the electronic hopping integrals by the phonons. The generalized coordinate of atomic displacement in $q$ basis is quantized in the standard way,

$$Q_q = \sqrt{\frac{\hbar}{2\Omega_q}} (a_q + a_q^\dagger),$$

where $a_q( a_q^\dagger)$ is the annihilation (creation) operator of the phonon mode $q$ and $\Omega_q$ is the frequency of the mode. However, the most natural way to couple this to real-space tight-binding basis is to make a transformation to the basis of real-space displacement of atom $\mu$ in the following way:

$$\hat{u}_\mu = \langle \mu | q \rangle Q_q,$$

where Einstein summation over phonon modes $q$ is implicit. Note that $\mu$ is a composite index denoting both the index of an atom and the direction of displacement.

Consequently, in tight-binding basis, this gives rise to a term in the Hamiltonian of the form

$$H_{el-vib} = \frac{1}{\sqrt{m_\mu}} \partial V_{\mu \delta} \hat{u}_\mu c^\dagger \alpha c_\beta = \Gamma_{\mu \delta} \hat{u}_\mu c^\dagger \alpha c_\beta,$$

where $V_{\mu \delta}$ is the hopping integral between orbitals $\alpha$ and $\delta$, and $R_{\mu}$ is the coordinate of atom $\mu$.

This coupling can be embedded into the electronic Hamiltonian as an energy-dependent self-energy. Following the arguments of Ref. 50, the general form of self-energy is written as

$$\Sigma_{\mu \delta}(\epsilon) = \frac{\hbar}{2} \Gamma_{\mu \delta} \sum_{\nu} \left[ \Omega_{\rho \nu} (1 - f(\epsilon - h \Omega)) + n_\nu(\Omega) G_{\nu \nu}^< (\epsilon + h \Omega) \right]$$

$$+ \frac{\hbar}{2} \Gamma_{\mu \delta} \sum_{\nu} \left[ \Omega_{\rho \nu} (f(\epsilon + h \Omega) - f(\epsilon - h \Omega)) + n_\nu(\Omega) G_{\nu \nu}^< (\epsilon + h \Omega) \right],$$

where $g_{\rho \nu}(\Omega) = <\rho\nu|\delta(\Omega - \Omega_{\nu})|q\nu>$ is an element of the vibration mode density matrix. Note again that we use Einstein summation convention so that summation is implied over orbital indices $\gamma$ and $\delta$ and the phonon polarization indices $\mu$ and $\nu$.

For simplicity, we now assume that: (i) the bosonic coupling only affects the $Cu d_{xz,yz}$ orbitals, where we include a diagonal self-energy of the form, $g(\Omega) = g\Omega^2$ when $\Omega = \Omega_d$ and it is 0 when $\Omega > \Omega_d$. For a Debye spectrum of phonons, $\Omega_d$ is the Debye cutoff frequency and the normalization factor is $g = 3/2\Omega_d^2$. (ii) $\rho_{\nu\nu} = -\frac{1}{2} \text{Im} G_{\nu\nu}^\gamma(\epsilon + h \Omega)$ is approximately a constant. This amounts to assuming that the electronic density of states is smoothly varying within the range of the phononic spectrum; and (iii) take $\Gamma_{\mu \delta} = \Gamma$, a constant parameter. Using these assumptions, the final form for the self-energy is

$$\Sigma^\gamma = -\frac{\Lambda}{\pi} \left( 2z + i\pi \right) \left( z^2 - 1 \right) \ln \left( \frac{z - 1}{z + 1} \right),$$

where $z = (\epsilon + i\eta)/(\hbar \Omega_{\nu})$, $\Lambda = \frac{3\hbar}{4\Omega_d^2}\Gamma \rho$, and $\eta$ is a convergence parameter. Although we have derived the preceding form for coupling to a 3D Debye spectrum of phonons, the results are not too sensitive to details of the spectrum and we would expect a similar result for an Einstein phonon or the magnetic-resonance mode.51

It is interesting to consider the asymptotic forms of self-energy as follows. If $\hbar \Omega_{\nu} \ll \epsilon$,

$$\Sigma(\epsilon) \approx -\Lambda \left( \frac{2}{\pi z} + i \right).$$

For large boson energies, i.e., $\hbar \Omega_{\nu} \gg \epsilon$, we obtain

$$\Sigma(\epsilon) \approx -\Lambda \left( \frac{4}{\pi z} + i z^2 \right).$$

While Eq. (A1) gives a general form of phononic self-energy for any pair of orbitals, in the present calculations, we adopt a few simplifications. First, we assume only diagonal terms of self-energy to make the model more tractable. Second, we apply Eq. (A2) to $Cu d_{xz,yz}$ orbitals using parameters $\hbar \Omega_{\nu} = 80$ meV and $\Lambda = 60$ meV. The former value gives the best fit to the peak-dip-hump structure and the latter controls the smoothness of the spectrum. In Fig. 6(c) we
make a comparison between the more general form of Eq. (A1) with the accurate density of states of Cu d_{x^2−y^2} orbitals. For the remaining orbitals we mimic a Fermi-liquid-type self-energy, which can be modeled with a \( \Sigma^r \approx e^\xi \) and \( \Sigma^i \approx \nu e^\xi \). Here we employ the asymptotic form of Eq. (A3), choosing parameters \( \hbar \Omega_c = 2.0 \text{ eV} \) (to ensure the correct asymptotic form for whole the energy range) and \( \nu = 100 \text{ meV} \). In this way, the need for a Kramers-Kronig transformation is avoided.

We can straightforwardly include in the self-energy the effect of magnon scattering responsible for the high energy kink. This will broaden the spectrum in the vicinity of the VHS peaks, thereby improving agreement with experiment in Fig. 6(a). It should be noted, however, that a more accurate modeling of the self-energy will be required both for the bosonic coupling and the Fermi-liquid term for treating the underdoped system.

**APPENDIX B: BOGOLIUBOV QUASIPARTICLES IN TIGHT-BINDING BASIS**

This appendix discusses aspects of the Bogoliubov transformation within a tight-binding basis. The Bogoliubov transformation is not explicitly carried out in the present calculations since the Green’s function tensor is obtained directly from Dyson’s equation. Nevertheless, understanding the relation between the transformation and the Green’s function tensor in the tight-binding basis is necessary for interpreting some of our results. In particular, our analysis of pairing symmetry is based on the relation between \( F_{\alpha \beta} \) and \( \langle c_{\alpha \dagger} c_{\beta} \rangle \).

The Bogoliubov transformation is conventionally carried out in a combined basis of spin-up electrons and spin-down holes,

\[
\mathbf{c}_k = \begin{pmatrix} c_{k \uparrow} \\ c_{-k \downarrow} \end{pmatrix}. 
\]  

These \( c \)'s diagonalize the one-particle Hamiltonian of Eq. (1) via the transformations

\[
c_{\alpha \dagger} = \langle \alpha | k \rangle c_{k \dagger} \]

and

\[
c_{\alpha \uparrow} = \langle k | \alpha \rangle c_{k \dagger} = \langle \alpha | k \rangle c_{k \dagger}
\]

or in a more compact form

\[
\mathbf{c}_\alpha = \begin{pmatrix} c_{\alpha \dagger} \\ c_{\alpha \uparrow} \end{pmatrix} = \begin{pmatrix} \langle \alpha | k \rangle & 0 \\ 0 & \langle k | \alpha \rangle \end{pmatrix} \mathbf{c}_k = B_{\alpha \beta} \mathbf{c}_\beta, 
\]

with inverse \( \mathbf{c} = B^{-1}_{\alpha \beta} \mathbf{c}_\alpha \).

This change of basis diagonalizes the one-particle Hamiltonian,

\[
e_k = \langle k | \alpha \rangle H_{\alpha \beta} \langle \beta | k \rangle 
\]

(with summation over \( \alpha \) and \( \beta \)). In this basis the Hamiltonian of Eq. (3) becomes

\[
H = e_k c_{k \dagger} c_{k \dagger} + e_k (1 - c_{-k \dagger} c_{-k}) + \Delta c_{k \dagger} c_{k \dagger} + \Delta c_{-k \dagger} c_{-k},
\]

now with summation over \( k \). After shifting this by a constant energy, it assumes the simple form

\[
H^\text{eff} = \mathbf{c}^\dagger \hat{H} \mathbf{c},
\]

where

\[
\hat{H} = \begin{pmatrix} e_k & \Delta_k \\ \Delta_k & -e_k \end{pmatrix},
\]

which can be diagonalized into

\[
H^\text{eff} = \mathbf{c}^\dagger U^{-1} \hat{H} U^{-1} \mathbf{c},
\]

where

\[
U = \begin{pmatrix} u_k & v_k \\ -v_k^* & u_k^* \end{pmatrix} \quad \text{and} \quad U^{-1} = \begin{pmatrix} u_k - v_k & v_k^* \\ -v_k^* & u_k - v_k \end{pmatrix}.
\]

The coefficients are chosen in the standard way in order to obtain a diagonal matrix

\[
U \hat{H} U^{-1} = \begin{pmatrix} E_k & 0 \\ 0 & -E_k \end{pmatrix},
\]

with \( E_k = \sqrt{e_k^2 + \Delta_k^2} \).

This Bogoliubov transformation introduces the quasiparticle basis

\[
\mathbf{a} = \begin{pmatrix} a_k \\ b_{-k \uparrow} \end{pmatrix} = U \mathbf{c}.
\]

Since we are working in the tight-binding basis, we end up with

\[
\begin{pmatrix} a_k \\ b_{-k \uparrow} \end{pmatrix} = \begin{pmatrix} u_k^* \langle k | \alpha \rangle & v_k \langle k | \beta \rangle \\ -v_k^* \langle k | \alpha \rangle & u_k^* \langle k | \beta \rangle \end{pmatrix} \begin{pmatrix} c_{\alpha \dagger} \\ c_{\beta \dagger} \end{pmatrix}
\]

(summation over \( \alpha \) and \( \beta \)) or inversely

\[
\begin{pmatrix} c_{\alpha \dagger} \\ c_{\beta \dagger} \end{pmatrix} = \begin{pmatrix} \langle \alpha | k \rangle u_k - \langle \alpha | k \rangle v_k \\ \langle \beta | k \rangle v_k^* - \langle \beta | k \rangle u_k \end{pmatrix} \begin{pmatrix} a_k \\ b_{-k \uparrow} \end{pmatrix}
\]

(summation over \( k \)).

We are particularly interested in writing the expectation values of electron and hole densities, \( \langle c_{\alpha \dagger} c_{\beta} \rangle \) and \( \langle c_{\alpha \dagger} c_{\beta} \rangle \), and pairing amplitudes \( \langle c_{\alpha \dagger} c_{\beta} \rangle \) and \( \langle c_{\beta \dagger} c_{\alpha} \rangle \) in terms of the Green’s function tensor. For this purpose, we start with a 2 \( \times \) 2 tensor

\[
\mathbf{c}_{\alpha \beta} = (B_{\alpha \beta} \mathbf{c}_\alpha B_{\beta \beta}^\dagger) = (B_{\alpha \beta} U^{-1} \mathbf{a} \mathbf{a}^\dagger B_{\alpha \beta}).
\]

Using the fact that \( \langle a_{\alpha \dagger} \rangle = -f(E_k) \) and \( \langle b_{-\beta \uparrow} \rangle = f(E_k) \), we evaluate each element of the tensor \( \mathbf{c}_{\alpha \beta} \) separately as follows:

(1) the number density

\[
\langle c_{\alpha \dagger} c_{\beta} \rangle = \langle \beta | k \rangle |u_k|^2 f(E_k) + |v_k|^2 (1 - f(E_k)) \langle k | \alpha \rangle.
\]

Now we use a trick following Ref. 54 where

\[
\langle \beta | k \rangle |u_k|^2 f(E_k) \langle k | \alpha \rangle = \int d\varepsilon \langle \beta | k \rangle u_{\delta \varepsilon} u^\dagger \langle k | \alpha \rangle,
\]

and
Hence

$$\delta (\varepsilon - E_k) = - \frac{1}{\pi} \text{Im}\left( \frac{1}{\varepsilon - E_k + i\eta}\right).$$

Using the trick of Ref. 54 again gives us the formula

$$\langle c_{\alpha}^\dagger c_{\beta}\rangle = \langle \alpha|k\rangle \left[f(E_k) - [1 - f(E_k)]|\alpha\rangle|\beta\rangle.\right.$$

Equations (B5) and (B6) also reveal how the anomalous part of the Green’s function tensor is related to the pairing amplitude $\langle c_{\alpha}^\dagger c_{\beta}\rangle$ in a tight-binding basis or equivalently how the anomalous part of the current is related to the making and breaking of Cooper pairs. In particular, symmetry properties of $F_{\alpha\beta}$ are seen to be related directly to those of $\langle c_{\alpha}^\dagger c_{\beta}\rangle$. 

14. Note that the tunneling signal decays exponentially with layer distance from the tip and therefore, we expect the results presented in this paper to be essentially the same for a semi-infinite solid.
The distinct VHS peaks in the computed spectrum are expected to be broadened to yield a smooth hump much like the experimental spectrum due to self-energy corrections resulting from magnetic response of the electron gas in the ~400 meV range. These self-energy corrections are not included in the present calculations.

Note that in solving the Dyson’s equation, the initial Green’s function for each k point is a diagonal matrix of complex Lorentzians. An infinite number of k points would be required for a final Green’s function without any artificial “shoulders,” although the imaginary part of the self-energy acts to smooth away the unwanted structures.

Although TP and TH are formulated in terms of LDOS, both approaches can, in principle, be decomposed into a spectral-function form since the density matrix can be decomposed in this way regardless of the basis set employed.

The decomposition of Eq. (8) into tunneling channels has been significantly elaborated beyond our recent work in Ref. 10. The most significant improvement is the explicit formulation of anomalous tunneling channels. Furthermore, we can obtain the total contribution of any chosen orbital over the whole infinite slab via the relation \( \sum'_{\nu} G_{\nu,\alpha}^\dagger G_{\nu,\alpha}' \), which is regular and anomalous terms of Eq. (17).

Note that the simulation cell indices 0 and i are explicitly written on the left-hand side.
